

Install WordPress from Scratch on a Server Using LEMP

This article provides an overview of WordPress. It also includes an in-depth tutorial on the installation of Nginx, MySQL and PHP-FPM, as well as how to deploy WordPress using LEMP.

And It's Security

WordPress is open source software that you can use to create beautiful websites, blogs or apps.

It is a content management system (CMS) written in PHP, and uses the MySQL and the MariaDB database. WordPress first appeared in 2003 as a joint effort between Matt Mullenweg and Mike Little. The latest version of it is 5.4 (Adderley), which was released in March 2020.

The features of WordPress are:

- Customisable designs
- SEO-friendly
- Responsive mobile sites

- High performance
- High security
- Powerful media management
- Easy and accessible

The LEMP stack

LEMP is a software stack that can be used to serve dynamic websites and Web applications.

It is an acronym that stands for the following:

- L -> Linux operating system
- E -> Nginx Web Server (Nginx is pronounced 'engine-x')
- M -> MySQL database server
- P -> PHP language

Prerequisites:

- You require the Linux server/ system. You can go with AWS EC2. Use T2.micro for testing purposes as it comes under the free tier.
- Any Debian based OS (I used Ubuntu OS).
- Root privileges to that server.
- Whatever domain or subdomains in use should point to the server.

Considerations:

- You have some domain/subdomain name (like *osfy-test.linuxgeek.in*) and that points to the server.
