

Zend Framework: A Tutorial

This tutorial on Zend covers various types of routers, routes and the creation of an admin module.

The main advantage of the Zend Framework is its modular structure, which is not dependent on any other part of the system. So you can replace and remove modules without affecting the whole system. We can say that the Zend Framework is a loosely coupled modular structure.

All about routing

Routing compares the request against all routes that have been defined in the configuration and returns a matched route array configuration. It also matches hosts, segments, literals and regular expressions and wildcard schemes. We can create parent and child route configurations. In Zend Framework 2, we need to specify all routes in *module.config.php* of each module.

Types of routers

1. **Literal:** This matches the exact URI path of the request. Each router has a default array that will be returned when

MVC events	
Event triggered	Details
Bootstrap	Executes at the beginning of request processing; we can execute some methods that we require before the actual logic of the code is executed, i.e., a pre-execution process.
Route	Matches request parameters with a specified list of routers, and identifies the controller and action to be redirected.
Dispatch	Actual logical code is executed.
Render	Based on all previous executions, it renders data on the interface.
Finish	Executes after completion of all MVC processes; we can call it a post-execution process.
