

Running a Web Server Inside a Docker Container

There are problems with setting up Docker when it is operated behind a proxy. This article explains how these can be overcome.

Wikipedia defines Docker as an open source project that automates the deployment of applications inside software containers, which are nothing but *isolated* user space instances running on an operating system. Docker makes use of the resource isolation features provided by the underlying Linux kernel, such as cgroups and kernel namespaces, so that multiple isolated instances can run on a Linux kernel without having a hypervisor layer installed.

This article offers a few tips to overcome CentOS7 based Docker set-up problems when it's operated behind a proxy. It tells you how to run a Web server inside a CentOS7 based container.

Setting up Docker in CentOS7, which runs behind a proxy

When you run Docker behind a proxy, you need to provide the proxy details to download the images. So let's get on with installing and setting up Docker on a CentOS7 machine (CentOS Linux release 7.0.1406 (Core) and kernel version is 3.10.0-123.20.1.el7.x86_64) when it runs behind a proxy. The detailed steps are as follows.

1. The very first step is setting up Yum with the proxy details. Add the following lines to `/etc/yum.conf`:

```
proxy=http://<proxy IP>:<port>
proxy_username=<User Name>
proxy_password=<Password>
```
