

The next step is to create a Gtk2 Builder object, and load the XML UI definition from the Glade file which we saved earlier:

```
$builder = Gtk2::Builder->new();
$builder->add_from_file("./employee-builder.glade");
```

Next, we connect the signal handlers we had defined in Glade, to functions defined in our Perl script, with the following command:

```
$builder->connect_signals(undef);
```

Our signal-handler functions are deliberately given names identical to the signal handler names we defined in Glade, so that the 'automatic' connection of the signal to the handler function can be done with the single line of code shown just above, instead of having to write several lines of code using the `g_signal_connect()` function to connect each widget's signal to the handler function for it. The signal-handler functions have the following functionality:

- **on\_window1\_delete\_event:** returns FALSE; as this is a simulation of an application, we don't have unsaved data to check for, and there's nothing for us to do with this function.
- **on\_window1\_destroy:** As mentioned earlier, we must end the Gtk2 main loop, so we simply call the `Gtk2->main_quit()` function here.
- **on\_cancel\_btn\_clicked:** Prints the function name, and calls `Gtk2->main_quit()` to signal the main loop to exit.
- **on\_ok\_btn\_clicked:** This function shows how to get the user input from the login and password text entry widgets, using the `get_text()` function associated with text entry objects. The values are printed to show that the text shown in the password field is not the content of the text entry object's buffer. In the real world, this code must be replaced by an authentication function.

## Run code, run...

Run the script with:

```
perl ./employee.pl
```

You can now verify that the code works as expected, and you have a working GTK program window controlled by a Perl script!

In the next article in this series, we will design and write code for the 'employee information viewer' screen. **END**
