

The ‘collections’ package in Python is a powerful tool to initiate text processing. It offers an alternative to Python’s general-purpose built-in containers — dict, list, set, and tuple.

This module implements specialised container data types, providing alternatives to Python’s general-purpose built-in

- *namedtuple()*: Factory function for creating tuple subclasses with named fields
- *deque*: List-like container with fast appends and pops on either end
- *ChainMap*: Dict-like class for creating a single view of multiple mappings
- *Counter*: Dict subclass for counting hashable objects
- *OrderedDict*: Dict subclass that remembers the order entries that were added
- *Defaultdict*: Dict subclass that calls a factory function to supply missing values
- *UserDict*: Wrapper around dictionary objects for easier dict subclassing
- *UserList*: Wrapper around list objects for easier list subclassing
- *UserString*: Wrapper around string objects for easier string subclassing

The collections package also provides the list data type with lots of methods like count, pop, popitems, index, and insert. A list of collection types must be declared initially before applying any methods from the collections package.

The output is:

```
print(userL.data)
```
