

Secure Your Network with Firewall Builder

A firewall isolates a trusted, secure internal network from another network like the Internet, which is not regarded as either trusted or secure. Firewall Builder is an open source product that makes it easy to configure firewalls.

In computing, hardening is the process of securing a system by reducing its areas of vulnerability. This is done by removing needless software, unnecessary logins and unnecessary services. There are various other methods of hardening, which may involve applying a patch to the kernel, closing network ports, setting up intrusion-detection/prevention systems and firewalls.

A firewall protects the resources of a private network from users of other networks. Organisations that allow their employees to access the Internet install a firewall to prevent unauthorised entities from accessing their own core services and core data, which is often confidential. Policy is the term often used in relation to firewalls. A policy can be described as a set of business rules or restrictions that are implemented with the use of a firewall.

One of the firewall's methods is to screen requests to make sure that they come from acceptable sources (domain names and IP addresses). Many companies make firewall

products that include features such as automatic alarms at given thresholds of attack, logging, reporting, and a graphical user interface to manage the firewall.

Firewall Builder has features such as a drag-and-drop GUI, shared objects and search-and-replace. It is available under GPL; its GUI is based on QT, and hence requires the QT runtime libraries and development packages if you wish to build from source.

Firewall Builder is based on the concept of objects. With this concept, users create objects such as IP networks and IP addresses to represent entities that will be used in firewall rules. Objects are stored in libraries. There are two object libraries that come with Firewall Builder. The User library stores objects that the user creates while the Standard library, which is a read-only library, contains hundreds of pre-defined objects such as common TCP and UDP services. Once you create a policy with firewall rules in Firewall Builder, the very next thing you need to do is
