

Flask: Flask is undoubtedly the most famous micro-framework for Python and a standout amongst the most well-known Python structures, period. Like Django, it was developed to get Web applications up and running as fast and effortlessly as possible. Regardless of its tiny size, Flask has been used by huge organisations, including LinkedIn and Pinterest.

In any case, here's the twist – since Flask is ideal for smaller, easier projects than Django, you can expect Web server development, support for Google App Engine and inbuilt unit testing. There is no database abstraction layer, form verification and validation, and auto upload features are disabled. However, every one of these features can be included via extensions. Some key setups incorporate SQLAlchemy for the database or Jinja2 for templating and CouchDB.

Some Python designers opt for Flask rather than Django on the grounds that the former is increasingly *pythonic*, in that, it generally adheres to the Python mantra of there being one approach to accomplish something, and that code ought to be clear about what it's doing. In case you prefer clean code from scratch, Flask might be a decent alternative.

Bottle: Bottle is another prominent micro-framework. It was initially developed for building Web APIs, which is still an excellent use case for it. What is more intriguing about Bottle is that it tries to execute everything in one single document, which should give you a brief idea of how micro it is designed to be.

The out-of-the-box functionalities include templating, routing, utilities, and some fundamental abstraction over the WSGI standard. Like Flask, you'll be coding significantly nearer to the metal than with a full-stack system. Regardless of that, Bottle has been employed by Netflix to create Web interfaces.

Other popular frameworks

We've gone through some of the most widely used Python systems, yet there are a variety of options you could choose from. We'll quickly take a look at a couple of others which could perform well in particular circumstances.

Tornado is a Python Web framework particularly developed to tackle the C10k issue (i.e., it can deal with over 10,000 simultaneous connections if properly configured) using asynchronous I/O. This gives it solid appeal for projects that require elite and countless concurrent users.

CubicWeb is an intriguing Web framework that is entirely different from the other frameworks. It's a piece of the semantic Web. In a layman's terms, it's a system that strives to display information in a way that is less demanding for PCs to get it. It replaces the model and view portion of MVC with a solitary concept – the data cube which can be used to develop different components, similar to Docker for the Web.

Phalcon is a micro-framework that is tied in with building cloud APIs. Like other micro-frameworks, it keeps minimal dependencies and maintains a strategic distance from complex features. However, unlike other systems, it wasn't developed for serving HTML pages. Rather, it's for building RESTful APIs quickly.

Even though Android has a remarkable SDK out-of-the-box, the implementation of Python instead of Java is a huge advantage for website and app development (using Kivy) since it offers quicker turnaround times and the reuse of Python libraries.

Python is a reliable and secure development language that is used for secure and agile Web app development. It is a standout amongst the available options, being the most dependable. It will reduce the development time spent trying to create a top-notch and robust Web app and site. You can consult with an experienced Python developer for your next project, for better guidance. **END**
